 3 *Samoa*

7

11

**Abstract**

12 Taro (*Colocasia esculenta* (L.) Schott) is a staple crop of many of the South Pacific nations with an  
 13 ever increasing export demand. In recent years, yields of taro have increased dramatically through  
 14 breeding and selection. However, selection of improved lines is often based entirely on final yield.  
 15 There are many physiological pathways by which increased potential yield may be achieved. Factors  
 16 such as the accumulation of dry matter and nutrient use efficiency, merit investigation.

17

18 Two improved (blight resistant) taro cultivars were planted and harvested for biomass measurements  
 19 on a monthly basis for a total of eight months (30-240 days after planting) through destructive  
 20 sampling. At each harvest, plants were separated into various plant parts and their dry matter  
 21 accumulation and nutrient content were determined. Since there were no significant differences in the  
 22 total and corm dry matter productions between the cultivars, it can rationally be said that cultivar Samoa  
 23 1 had a higher nutrient use efficiency, (kg of edible dry matter produced per kg of nutrient taken up),  
 24 for N, P, K, Mg, Mn and Cu over cultivar Samoa 2. However, for Ca, Fe and Zn, it is logical to consider  
 25 that cultivar Samoa 2 had a higher nutrient use efficiency over cultivar Samoa 1.

26

28

29 **Introduction**

30 Root and tuber crops are the major sources of  
 31 dietary energy for many people in the Pacific  
 32 island countries. In the Pacific Islands, taro  
 33 has always been richly woven into the fabric  
 34 of life. Taro is postulated to have originated in  
 35 southern or south-east Asia, and to have been  
 36 dispersed to Oceania through the Island of  
 37 New Guinea very many centuries ago. The  
 38 crop has evolved with the cultures of the  
 39 people of the Asia/Pacific region. Not  
 40 surprisingly, it has acquired considerable  
 41 socio-cultural importance for the people.  
 42 Among the food crops in Oceania region, the  
 43 adulation and prestige attached to taro is  
 44 equalled only by yam in certain localities.

45

46 In most studies with food crops, biomass  
 47 production and nutrient uptake receive little  
 48 attention, particularly due to the tedious and  
 49 difficult nature of the quantification process.  
 50 This has led to a scarcity of basic information  
 51 regarding dry matter accumulation and  
 52 nutrient uptake for the taro crop, particularly  
 53 under intensive cropping systems which are  
 54 aimed at satisfying the crop demand of a  
 55 growing population and supplying corms for  
 56 export markets. An essential step to increase  
 57 the efficiency of fertilisers in order to improve  
 58 yields is an understanding of nutrient uptake  
 59 and allocation within the taro plant during the  
 60 growing season. These data are essential for  
 61 the development of technological packages,  
 62 especially involving nutrient inputs, growth

63 simulation models, and decision support  
64 system. This information is also critical for the  
65 establishment of taro breeding programs  
66 aimed at raising the yield potential of taro.

67

### 68 **Research objective**

69 The objective of this research is to investigate  
70 the dry matter accumulation and nutrient use  
71 efficiency for two improved taro cultivars  
72 grown under semi-controlled screen house  
73 environment, through regular temporal  
74 destructive sampling.

75

### 76 **Materials and methods**

#### 77 *Description of the trial*

78 This experiment was conducted to investigate  
79 the nutrient uptake of the two improved  
80 (blight resistant) taro cultivars grown for the  
81 fallow experiment, *Samoa 1* and *Samoa 2*.  
82 The experiment was executed under the semi  
83 controlled environment of a screen house,  
84 with the taro being grown in pots. The soil  
85 used was a well-drained Inceptisol (Oxic  
86 Humitropept, clayey-skeletal oxidic  
87 isohyperthermic) with pH = 6.0; organic  
88 carbon = 3.2%; and exchangeable bases =  
89 10.3 cmol(+)/kg of soil. The soil was air dried  
90 and sieved through a 1 cm mesh. The potting  
91 bags were filled with 10 kg of soil each.

92

#### 93 *Nutrient supplementation and incubation*

94 The entire package of **macro and**  
95 **macronutrient elements**, based on the soil pH,  
96 was included for nutrient supplementation to  
97 each pot, carried out at recommended levels  
98 **by** Asher *et al.* (2002) (Table 1). An  
99 incubation time of two weeks was allowed  
100 before the planting of the two taro varieties.

101

#### 102 *Experimental design, layout and size*

103 Suckers of two improved taro cultivars,  
104 *Samoa 1* and *Samoa 2*, were planted in pots  
105 and laid out in a split-plot arrangement, using  
106 randomised complete block design with five  
107 replications. Each replication consisted of two  
108 main plots as the cultivars which were split to  
109 accommodate eight monthly biomass

110 harvests, sampled for dry matter accumulation  
111 and nutrient uptake at different stages of plant  
112 growth. There were six data plants of each  
113 variety from each block (each sub-plot) for  
114 each of the eight harvests totaling to 240  
115 plants for each cultivar (480 plants for the  
116 whole experiment). The cultivars and harvests  
117 were completely randomised within a block.

118

#### 119 *Data collection*

120 Six taro plants of each cultivar from a block  
121 were harvested at 30, 60, 90, 120, 150, 180,  
122 210, and 240 days after planting (DAP), to  
123 ascertain the dry matter measurements and  
124 total chemical analysis of individual plant  
125 parts. Plants in the sub-plots were harvested,  
126 washed and separated into petioles, corms,  
127 roots and sucker components. Samples of the  
128 various plant parts were oven dried to a  
129 constant weight at 65°C for dry matter  
130 determination. The dried samples were  
131 ground to pass through a 1.0-mesh screen and  
132 analysed for N, P, K, Ca, Mg, Fe, Mn, Cu and  
133 Zn. The third most upper leaf lamina was also  
134 analysed for these elements at 30, 60, 90, 120,  
135 150, 180, 210, and 240 days after planting  
136 (DAP). Nitrogen was determined by the  
137 micro-Kjeldahl procedure (IBSNAT, 1987), P  
138 by molybdovanadophosphoric acid (IBSNAT,  
139 1987), and K, Ca, Mg, Zn, Fe, Mn, and Cu by  
140 atomic absorption spectrophotometry  
141 (Chapman and Prat, 1961; Prasad and Speirs,  
142 1978). **Nutrient content** were calculated as the  
143 product of dry matter content and tissue  
144 nutrient concentration.

145

#### 146 *Statistical analysis*

147 All the data collected were subjected to  
148 analysis of variance **using ANOVA** for split  
149 plot treatment arrangement laid out in a  
150 randomised complete block design structure.  
151 Best-fit curves were determined using  
152 polynomial regression procedures of the  
153 Genstat Statistical Software package (VSN  
154 International Ltd., 2016). Only coefficients  
155 significant at  $P < 0.05$  were retained in the  
156 model.

157

158 Table 1 Typical rates of nutrient supplementation for soils with a pH of 6.0

| Element | Rates of application of element (kg/ha) | Compound  | Molecular weight | Weight conversion factor - element to salt | Rates of application of salt (kg/ha) | Concentration of stock solution (g salt/L) |

160

161 **Results and Discussion**

162 *Dry matter accumulation by various plant*  
 163 *organs*

164 The accumulation of dry matter by various  
 165 plant organs of the two cultivars is illustrated in  
 166 Figure 1a-f. Total dry matter did not differ

167 significantly between cultivars throughout the  
 168 experimental period (Table 2). The first 90  
 169 days after planting (DAP) were characterised  
 170 by low rates of total dry matter production by  
 171 both the cultivars (Figure 1a). During this  
 172 period, leaves and petioles accounted for 58%

173 of the total dry matter produced in each cultivar  
 174 (Figure 1a-c). Following 210 DAP, the dry  
 175 matter content in the leaves and petioles  
 176 declined to less than 25% of the total dry  
 177 matter, but it increased significantly in corms  
 178 and suckers (Figure 1e and f). During the first  
 179 90 DAP, roots of cultivars Samoa 1 and Samoa  
 180 2 represented about 13% and 18% of the total  
 181 dry matter content, respectively. Following 180  
 182 DAP, the dry matter content in the roots was  
 183 never higher than 8% for Samoa 1 and 12% for  
 184 Samoa 2. Cultivar Samoa 2 accumulated  
 185 significantly higher root dry matter than Samoa  
 186 1 throughout the experimental period. It is  
 187 noteworthy that, between 150 and 240 DAP,  
 188 the suckers were a significant sink of dry matter  
 189 in the taro plant. During this period, these  
 190 organs accounted for 22% of the total plant dry  
 191 matter in Samoa 1 and 13% in Samoa 2. These  
 192 results are of particular importance because,  
 193 when taro is grown under upland conditions,  
 194 cormels of suckers seldom reach a marketable  
 195 size; and they may compete for assimilates  
 196 with the marketable main corm. Maximum  
 197 significant dry matter accumulation in the  
 198 corms of both the cultivars was recorded  
 199 between 210 and 240 DAP, accounting for  
 200 about 46% of the total plant dry matter.

201  
 202 *Nutrient uptake of the two taro cultivars as*  
 203 *influenced by plant age*

204 Except for P, Mg and Zn, there was no  
 205 statistical significance between the cultivars for  
 206 the quantity of nutrients taken up by plants  
 207 (Table 2). In general, the nutrient uptake was  
 208 very similar between cultivars during the first  
 209 150 DAP; thereafter, the quantity of all the  
 210 nutrients taken up by plants of cultivar Samoa  
 211 1 was lower than that of cultivar Samoa 2,  
 212 however, only significant for P, Mg and Zn.  
 213 The only exception was for Fe uptake where  
 214 uptake by cultivar Samoa 1 was higher than

215 cultivar Samoa 2, however, this was not  
 216 significant (Figure 2a-e and Figure 3 a-d).  
 217 Maximum uptake values for the two cultivars  
 218 are given in Table 3.

219  
 220 *Maximum levels of nutrient uptake by the two*  
 221 *cultivars (kg/ha)*

222 It is noteworthy that cultivar Samoa 1 plants  
 223 absorbed 20% less K and 17% less N than those  
 224 of cultivar Samoa 2 with the uptake uniformly  
 225 distributed over the entire life cycle of the crop.  
 226 These results also confirms that, as with most  
 227 root crops, taro has a high requirement for K  
 228 relative to N (Goenaga and Chardon, 1995;  
 229 Norman *et al.*, 1994). Mergedus *et al.* (2014)  
 230 also reported analogous findings with the corm  
 231 being characterised by high concentrations of  
 232 K.

233  
 234 The third uppermost leaf laminar is often used  
 235 to determine the nutritional status of aroid  
 236 crops including taro (Goenaga and Chardon,  
 237 1995). In general, the concentrations of all the  
 238 nutrients except Fe in the leaf laminar of  
 239 cultivar Samoa 1 plants had greater  
 240 concentrations than cultivar Samoa 2 plants.

241  
 242 Since there were no significant differences in  
 243 the total and corm dry matter productions  
 244 between the cultivars (Table 2), it can  
 245 rationally be said that cultivar Samoa 1 had a  
 246 higher nutrient use efficiency, (kg of edible dry  
 247 matter produced per kg of nutrient taken up),  
 248 for N, P, K, Mg, Mn and Cu over cultivar  
 249 Samoa 2. However, for Ca, Fe and Zn, it is  
 250 logical to consider that cultivar Samoa 2 had a  
 251 higher nutrient use efficiency over cultivar  
 252 Samoa 1 (Figure 4 and Figure 5). Mergedus *et*  
 253 *al.* (2014) concluded that the effect of the taro  
 254 genotype was significant for more than half of  
 255 the analysed minerals (i.e., Mg, Ca, Zn, Fe,  
 256 Mn).

330 **Conclusions**

331 The availability of essential nutrients has been  
 332 identified as a major limitation to crop  
 333 productivity in many regions of the tropics.  
 334 Inorganic fertilisers are seldom applied under  
 335 traditional farming practices in developing  
 336 nations, because of their high cost and uncertain  
 337 availability. Instead, productivity is often  
 338 maintained by employing systems of bush  
 339 fallowing, and within a cropping phase, by  
 340 rotations to match nutrient demand by a crop to  
 341 soil fertility. However, growing populations and  
 342 export potential have resulted in a need to  
 343 increase the productivity of many staple food  
 344 crops. Therefore, investigations into nutrient use  
 345 efficiency of improved varieties, merits  
 346 attention.

347

348 This investigations revealed that while the  
 349 concentrations of all the plant nutrients  
 350 (except Fe) uptake was higher for cultivar  
 351 Samoa 2 than cultivar Samoa 1, the nutrient  
 352 use efficiency (kg of edible dry matter  
 353 produced per kg of nutrient taken up) for  
 354 cultivar Samoa 1 was higher for N, P, K,  
 355 Mg, Mn and Cu over cultivar Samoa 2.  
 356 However, for Ca, Fe and Zn cultivar Samoa  
 357 2 had a higher nutrient use efficiency over  
 358 cultivar Samoa 1.
